Security, extensibility, and redundancy in the Metabolic Operating System

Samuel T. King University of California, Davis

Abstract—People living with Type 1 Diabetes (T1D) lose the ability to produce insulin naturally. To compensate, they inject synthetic insulin. One common way to inject insulin is through automated insulin delivery systems, which use sensors to monitor their metabolic state and an insulin pump device to adjust insulin to adapt.

In this paper, we present the Metabolic Operating System, a new automated insulin delivery system that we designed from the ground up using security first principles. From an architecture perspective, we apply separation principles to simplify the core system and isolate non-critical functionality from the core closed-loop algorithm. From an algorithmic perspective, we evaluate trends in insulin technology and formulate a simple, but effective, algorithm given the state-of-the-art. From a safety perspective, we build in multiple layers of redundancy to ensure that the person using our system remains safe.

Fundamentally, this paper is a paper on real-world experiences building and running an automated insulin delivery system. We report on the design iterations we make based on experiences working with one individual using our system. Our evaluation shows that an automated insulin delivery system built from the ground up using security first principles can still help manage T1D effectively.

Our source code is open source and available on GitHub (link omitted).

1. Introduction

Biohacker /'bīō,haker/ Noun

- A person who manipulates their metabolic state using sensors, injected hormones, nutrients, physical activity, computer systems, and artificial intelligence.
- An enthusiastic and curious person who learns about their own biology and metabolism through experimentation on them self.
- A person who uses computers to gain access to someone's metabolic state.

There are 8.4 million people living with Type 1 Diabetes (T1D) worldwide [19] and they are all biohackers.

T1D is a metabolic disorder where people's immune systems attack their pancreas and kill the cells that produce insulin. Insulin is a hormone that transports glucose (sugar) from the blood stream to muscles, the liver, the brain, and other places where the body uses it for energy. When people eat, their digestive system converts food into glucose, which

makes its way into their blood stream. Since people with T1D are unable to produce their own insulin, they inject synthetic insulin, and they play the role of the pancreas in their metabolic system.

Managing T1D is hard. First, each time a person living with T1D eats, they need to make their own dynamic dosing decisions [38]. This process requires considering their current metabolic state, food, insulin, exercise, stress, caffeine, and so on to come up with an accurate prediction for how their blood glucose will respond to the meal and injected insulin. Then, they need to match the timing of the insulin injection with the timing of when food digests and causes glucose to enter the blood stream. Finally, after the process of injecting insulin and eating is done, they need to track their blood glucose level for hours afterward to make sure that they got it right and adjust if they got something wrong. And this process repeats every time they eat – meals, snacks, desert, anything – causing a substantial cognitive load to manage T1D.

Second, insulin is a dangerous hormone and can kill people. Taking too much insulin can kill people in a matter of hours [14] and taking too little insulin can kill people in a matter of days [5]. People with T1D need to walk a delicate balance with insulin dosing and food to avoid serious consequences.

Third, after people living with T1D learn how to *not* die, even less severely imbalanced glucose levels can still cause long-term health complications. These complications include heart disease, stroke, kidney failure, blindness, nerve damage, amputations, and impotence (in men), just to name a few [13], [18]. The best way to avoid these long-term health complications is to manage tight control of glucose levels.

Technology and biohacking help to manage T1D. Changes in diet can help provide more predictable glucose responses after eating [23]. Continuous Glucose Monitors (CGMs) track glucose levels using implanted sensors to facilitate real time treatment adaptations [33]. And automated insulin delivery software can connect these CGM readings with an insulin pump for automatic insulin dosing [6], [12], [11].

Biohacking presents both a challenge and an opportunity for systems software. The challenge is that stakes are high, people's lives and long-term health depend on the software they use for biohacking when managing T1D, so simplicity, security, and correctness are all critical. If we can solve this challenge, the opportunity is to create extensibility mechanisms so that people can add to biohacking software safely and create an ecosystem of apps that accelerate innovation for managing T1D.

We introduce a new system, the Metabolic Operating System (MOS), that we built for biohacking and managing T1D. Our innovation is in the architecture we use to implement T1D management features. We use separation principles from the OS and microkernel areas [1], [22] applied to the application layer for strong isolation and simplicity of our software components, similar to secure web browsers [20], [43], [42], [35]. In our design, we define biohacking abstractions, we decompose the system into isolated modules, and expose narrow and well-defined interfaces. These interfaces help provide the anchor for our security policies and form the foundation for our extensibility mechanisms.

At the heart of our design is our *BioKernel*, which manages the CGM and insulin pump hardware that we use in MOS. The BioKernel also runs the novel closed-loop algorithm we design for automated insulin delivery. Finally, the BioKernel produces the event logs that other apps use to infer the state of the system, which is the core of our extensibility abstraction.

To demonstrate extensibility, we build four apps on top of MOS. Our apps handle the full life cycle of T1D management: food entry, therapy settings ML and analysis, a replay app, and a Metabolic Watchdog that monitors the person's metabolic state to predict high or low glucose levels. These apps all run in isolation, consume log data, and interact with the BioKernel using a trusted UI.

Using the Metabolic Watchdog app on one individual, we show a clinically significant improvement to their core metabolic health metrics. We report on one year's worth of data, including four months of treatment using MOS and the Metabolic Watchdog. Our results show an improvement in the individual's Glucose Management Index [7], a core measure of metabolic health for people living with T1D. Their Glucose Management Index went from 6.8% at its peak to 5.8% using MOS, which is 2.6x greater than the average improvement experienced by adults switching to fully automated insulin delivery systems [9].

Using the lessons learned from the Metabolic Watchdog, we design and implement an automated insulin delivery system for injecting insulin automatically using software. We report on one week's worth of data for one individual and our results show that we maintain the tight control we achieved with the Metabolic Watchdog while reducing the cognitive load of managing T1D.

To the best of our knowledge, our contributions are:

- MOS is the first system to improve security for biohacking software by applying separation principles and redundancy for a practical system.
- We take a clean-slate approach to automated insulin delivery systems and build a new system to show how we can keep our implementation simple while still providing the ability to manage T1D.
- We implement a novel T1D treatment app on MOS, the Metabolic Watchdog, and a closed-loop insulin delivery system and demonstrate their effectiveness on one individual.

2. Broader trends

Two broader trends suggest that now is the time for the research community to invest in systems for biohacking. First, metabolic disorders are an epidemic worldwide, with more than 133 million people who have Prediabetes or Type 2 Diabetes in the US alone [16], which brings with it severe health consequences [15]. Although our focus is on T1D, we believe that MOS presents a first step towards software for managing metabolic disorders in general using technology and biohacking securely.

Second, CGM technology for monitoring glucose levels are invasive today, but research has shown that non-invasive sensors have the potential for use in practice. Sensors for measuring glucose levels using tears [4], sweat [29], and optical sensors [41] all have the potential to make available real time glucose measurements without needing to place sensors beneath the skin, as is required with today's CGM technology. With these non-invasive sensors we anticipate broader use, and with broader use we will need software to help people manage their metabolic health securely, which is the focus of this paper.

3. Problem statement, threat model, and assumptions

We address the problem of designing and implementing secure iOS apps for controlling hardware that people use to manage T1D. This hardware includes CGM sensors for reading real time glucose levels and an insulin pump for injecting insulin. Our main security goals are integrity and always having safe fallback states.

In our threat model, we consider attacks originating from other apps and from network attackers. We assume that the underlying operating system is secure and upholds its stated isolation abstractions. We also assume that the CGM and insulin pump devices we use are correct and that the Bluetooth pairing process establishes a secure wireless channel between these devices and the phone. Availability attacks at the Bluetooth or iOS level are out of scope for this paper, but we do configure the insulin pump to have safe defaults in case availability attacks do occur.

4. MOS design and implementation

This paper describes our design for MOS, a system for trustworthy automated insulin delivery; we have three primary goals. First, we want the software that interacts with the insulin pump and CGM to be simple. With simplicity comes the ability to reason about its correctness and reduces the likelihood of bugs or vulnerabilities. Second, despite this simplicity we want to support rich functionality overall, in line with what existing automated insulin delivery systems support today. Third, we should have the ability to monitor the health of both our software and the human using it.

This section describes our design and implementation for MOS that strives to achieve these goals. We lay out the principles that guide our design, describe the overall architecture, and then discuss each of the main components. Section 7 describes the algorithm design and implementation for managing T1D, this section focuses on the systems and software architecture.

4.1. Design principles

In our overall design we decompose the task of automated insulin delivery into several isolated components and provide abstractions for these components to communicate. Together these components make up the overall MOS system. Three principles guide our design:

- Push complexity to non-critical components. In our system, the software that interacts with the CGM and insulin pump hardware is the most critical. Thus, we push complexity away from this core software as much as possible to less critical subsystems.
- 2) Ensure that the pump is always in a safe state. This principle guides both how we interact with the insulin pump automatically and how we handle the case where the pump becomes disconnected from the phone.
- 3) Use the longer timescales of biological systems to simplify software. Biological systems operate on longer timescales (O(hours)) than typical computer systems. We use these longer timescales to look for opportunities to simplify our software further when we can do so safely.

4.2. Overall architecture

Figure 1 shows our overall system architecture. At the core of our overall architecture is an iOS app, called the BioKernel. The BioKernel is the component that interacts with the CGM and insulin pump hardware, runs the closed-loop dosing algorithm, and produces event logs that other components use to learn the state of the system. Although the BioKernel can run as a stand-alone app that implements automated insulin delivery, we provide only a bare minimum set of features in this core app to keep it simple.

To support rich functionality, the BioKernel stores its event logs in a cloud-based service, which is then consumed by other apps, and exposes trusted UI views. Among the other apps that use these event logs are a Metabolic Watchdog for monitoring the individual's metabolic state, an app for replaying the closed-loop algorithm execution to verify its results, an app (Loop) for meal announcements and manual insulin dosing, and an app for running machine learning on the data to update therapeutic settings. Apps dose insulin and update settings through trusted UI components running within the BioKernel app.

Figure 2 shows how some of these components interact while the individual using MOS takes an insulin dose before eating a meal (called a *bolus*). First, the individual opens the Loop app, which gets the latest glucose and insulin

Figure 1. Overall architecture for MOS.

state from event logs. The individual enters the number of carbohydrates they will eat, and based on this data Loop recommends an insulin dose. Once the individual chooses an insulin dose, they press the "Save and deliver" button. Second, the button press uses an iOS Universal Link to display the BioKernel's insulin dosing view, which shows the individual how much insulin it is going to deliver and gives them an opportunity to make changes. After they press the "Deliver" button, the BioKernel runs a FaceID check and delivers the insulin by programming the insulin pump.

After the initial dose, the BioKernel and the Metabolic Watchdog monitor and adjust as needed. The BioKernel reads in the latest glucose readings from the CGM in the background and adjusts the insulin dosing as needed to maintain glycemic balance. Glycemic balance means that the individual's glucose stays between 70 mg/dl and 140 mg/dl – not too high and not too low. The Metabolic Watchdog monitors glucose levels using event logs to predict glycemic imbalance, alerting the individual if it detects anything. Section 7 details the algorithms and mechanisms we use for adjusting insulin dosing and predicting glycemic imbalance.

One implementation decision worth noting is storing our event logs in a cloud-based service. In our original design, everything ran on device for both improved privacy and availability. However, iOS is a general-purpose OS and its current abstractions mismatched what we needed in terms

User initiated meal announcement

Background monitoring after the dose

Metabolic watchdog glucose predictions

Figure 2. Dosing (bolusing) for a meal example.

of background execution (see Section 7.4 for more details). Thus, we view the cloud-based event logs as an artifact of our current implementation as opposed to a fundamental aspect of our overall architecture. With the right OS-level interfaces, we believe that everything can run on device.

4.3. The BioKernel

At the center of the MOS is our BioKernel. The BioKernel manages the CGM and insulin pump hardware, runs the closed-loop insulin dosing algorithms, and saves event logs to the event log service to enable other apps to recreate its state and extend its functionality.

This section provides an overview of the BioKernel UI and subsystems and discusses how we keep our implementation simple.

4.3.1. The BioKernel UI and subsystems. Although our design and implementation support extensibility, the BioKernel can serve as a stand-alone automated insulin delivery system. Figure 3 shows the main UI for the BioKernel, which provides the most recent glucose reading from the CGM, diagnostic information, an alarm interface, and a 12-hour chart of the individual's glucose readings. From this

Figure 3. The main user interface for the BioKernel.

main UI, the individual can configure their therapeutic settings, change their pump or CGM, view summary statistics of recent glucose readings, or deliver an insulin dose.

Behind the scenes, the BioKernel consists of five main subsystems (Figure 4). First, the BioKernel uses LoopKit [27], an open-source library, for device drivers to interact with the underlying CGM and insulin pump hardware. Second, the BioKernel implements glucose, insulin, therapeutic settings, and alarm services that ingest events from the LoopKit drivers and provide abstractions to the rest of the BioKernel. Third, the closed loop run time queries the abstraction services and runs through the closed-loop calculation to update insulin delivery. Fourth, the BioKernel provides trusted UI components that other apps can invoke using Universal Links to update therapeutic settings or to dose insulin. Fifth, the BioKernel event logger sits in between the LoopKit drivers and BioKernel abstraction services to log these events.

4.3.2. Keeping the BioKernel simple. The most important aspect of our design and implementation is keeping the BioKernel's implementation simple. With simplicity it is easier to reason about correctness and we reduce the likelihood of bugs and vulnerabilities. In this section, we highlight the main mechanisms we use to keep the BioKernel's implementation to a minimum. Section 8.4 quantifies

Figure 4. The primary BioKernel internal subsystems.

our efforts to simplify the BioKernel.

The most impactful mechanism we use for simplicity is logging events and providing other apps with interfaces to interact with the BioKernel. Through this extensibility mechanism, we can support the features that one would expect in an automated insulin delivery system while keeping the BioKernel itself relatively simple.

The next impactful mechanism for simplicity is through rethinking core closed-loop algorithms with the recent advent in ultra-fast acting insulin. Section 7.2 outlines the impact of this observation on our algorithm formulation, but the gist of it is that with faster acting insulin we can remove core abstractions, predictions, and simulation functionality typically found in automated insulin delivery systems to simplify the BioKernel.

Another impactful mechanism for simplicity is that ultimately, our software impacts a biological system (the human injecting insulin), which operates and longer timescales. Because we know we have O(hours) until adverse effects take place, we can push some of our verification tasks and correctness checks outside of the BioKernel. Our closed-loop replay app demonstrates this principle in action (Section 4.7).

From an implementation perspective, we use Swift's Structured Concurrency for simplified multithreading support, we use flat files in the local file system to store serialized JSON objects rather than Apple's CoreData SQL interface or HealthKit. We minimize caching, opting to recompute values rather than managing caches. All in all,

these small implementation details add up to an overall system that is easier for people to understand and reason about.

4.4. Managing insulin pump and CGM hardware

In MOS we support one insulin pump: the Omnipod Dash. The BioKernel communicates directly with the Omnipod Dash via Bluetooth low energy, and the Omnipod Dash supports three main commands for injecting insulin. The first command injects a specified amount of insulin effectively immediately. People use this command to inject a calculated dose to cover meals typically. The second command sets a low background rate of constant insulin injection. The physiological basis for setting a rate is that the human body produces glucose constantly to supply energy to the brain, muscles, liver, and anywhere that needs it. This baseline rate covers the insulin needs for this background glucose production. The third command temporarily overrides the baseline rate with a specified new rate and duration.

In the BioKernel, we change insulin by adjusting the baseline insulin delivery rate temporarily each time we get a new CGM reading. Section 7.3 describes our algorithm for making these adjustments, but conceptually if the individual needs more insulin, we increase the rate. If they need less, we decrease it.

By changing the baseline insulin delivery rate temporarily, we get three desirable safety properties. First, if our software has a bug and sets the baseline insulin delivery rate twice, it has no impact – it is just a rate. In contrast, injecting twice delivers twice the insulin, which we would like to avoid. Second, we configure the pump with a maximum allowed rate, so that the pump hardware limits the amount of insulin that the BioKernel can inject, keeping it small enough for the individual using it to correct easily by eating glucose if needed. Third, if the pump becomes disconnected from the phone, the temporary rate defaults back to the prespecified baseline rate after the temporary rate command expires, providing safety for the individual.

Our general guidelines for pump configurations are to set the maximum rate equal to 4x the baseline rate and always use a 30-minute duration for our temporary rate commands. These settings enable us to move fast enough to correct glycemic imbalance while ensuring that we limit the amount of insulin that we can inject automatically. It is worth noting that this general safety strategy comes from the OpenAPS [30] and Loop [26] open-source automated insulin delivery systems, which we adopt in MOS.

In MOS, we support two CGM devices: the Libre 3 and Dexcom 7 CGMs. Both devices come with separate stand-alone apps that manage the CGM, which we are in favor of from an architectural perspective. The reason that we like this design is because these CGM apps have a slew of functionality that they implement that is useful, like providing parents with the ability to track their kid's glucose in real time, but that we prefer to keep out of the BioKernel.

The BioKernel communicates with the Dexcom 7 using Bluetooth low energy and communicates with the Libre

3 using a network service. Although our current version supports both, soon we will drop support for the Libre 3 in favor of the Dexcom 7 to avoid creating a dependency on a network service and instead support only CGMs that we communicate with directly using Bluetooth low energy.

4.5. Event logs

One interesting design decision for event logs is at what layer of abstraction to log events. The tradeoff is lower in the stack (i.e., closer to the hardware), the more software state you can reproduce, but the harder it is to work with the logs.

In our current implementation we log at the interface between the LoopKit drivers and our core abstractions for facilitating closed loop operation. This layer of abstraction is relatively high, meaning that it is easy for apps to consume an infer the state, but we can only reproduce high-level abstractions. In future work we will also log the Bluetooth low energy messages to recreate the full software stack.

Our event logs hold events for the CGM, closed-loop algorithm runs, and insulin pump events. CGM logs are the most straightforward consisting only of a timestamp and glucose reading. Closed-loop algorithm runs include the inputs to the closed-loop algorithm, current therapeutic settings, and the result. The pump events include all the commands that the BioKernel issued to the pump and pump alarms in case there is an issue that requires the individual's attention. This data enables the apps that run on top of MOS.

4.6. Extending the BioKernel with Loop

Loop is another open-source automated insulin delivery system. Loop provides functionality for helping calculate the amount of insulin needed when one eats, tracking the absorption of that food as it converts to glucose, and predicting how the individual's metabolic state will evolve over the next six hours.

The interesting part about using Loop in MOS is that it is an app written by someone else that we ported to run within MOS. The way we support Loop is by creating virtual CGM and insulin pump devices and then replaying our event logs to keep Loop's view of the state consistent. This implementation for Loop allows us to use it for calculating insulin doses, keeping track of carbohydrates, and predicting future metabolic state while still using the BioKernel to run our own closed-loop algorithm in a separate and isolated protection domain.

4.7. Apps for redundancy and refinement

The other three apps in MOS, the Metabolic Watchdog (Section 7.1), settings analytics, and closed-loop replay apps are all apps written by us to support the overall functionality of MOS, with the Metabolic Watchdog and closed-loop replay apps providing redundancy to our system.

Architecturally, the closed-loop replay app provides an interesting example of pushing complexity outside of the

BioKernel and taking advantage of the longer timescales available when interacting with biological systems. Our closed-loop replay app has a Python implementation of our closed-loop algorithm. We run it and check the results with the event logs to confirm that the closed-loop algorithm is running as expected. In our implementation, we also include a slew of sanity checks that make the source code a bit messy and add complexity but are nice to have to confirm our assumptions. If this app detects any inconsistencies, it notifies the individual and they have plenty of time to adapt, if needed.

4.8. Humans also provide redundancy

In addition to all the automatic systems we have in place with MOS, the human that uses MOS can also detect glycemic imbalance or potentially dangerous situations. For example, the individual who used MOS, who we will call Bob, can sense both hypoglycemia (low glucose, below 70 mg/dl) and hyperglycemia (high glucose, above 200 mg/dl). When Bob's glucose goes low, he feels simultaneously slightly drunk and panicky. When Bob's glucose goes high, he gets a burning sensation in his feet. Since people living with T1D deal with glycemic imbalance often, they can learn to feel when it happens.

Additionally, Bob can feel insulin doses. When he injects insulin to cover a meal, he gets a slight burning sensation at his pump insertion site. Fortunately, he does not feel the background basal that his pump injects. But by knowing when his pump is injecting insulin, he can provide a backstop against the most egregious errors that can happen with automated insulin delivery systems.

Our goal is to make sure that we avoid glycemic imbalance and spurious injections, but if it does happen most people living with T1D will be able to know about it.

5. Background on T1D physiology

In this section, we outline the basics of human physiology for people living with T1D. We cover food, digestion, and glucose, insulin, insulin therapy for T1D, and important glucose levels. We introduce these concepts to help provide background for our T1D management strategy (Section 6) and our closed-loop algorithmic formulation (Section 7).

5.1. Food, digestion, and glucose

At a high-level, we can divide food into three macro nutrients: carbohydrates, fat, and protein. These macro nutrients provide the body with energy via glucose.

The main macro nutrient of interest to people living with T1D are carbohydrates, or carbs. Carbs are sugar molecules and of the macro nutrients have the largest impact on one's glucose. When people eat carbs, they can take anywhere from 40 minutes to digest and convert into glucose in your blood stream, or up to three hours depending on what else you ate with them and how much your body needs to process the carbs to turn them into glucose.

Fat and protein also convert to glucose, but at a much lower volume per gram and much more slowly, taking five hours or more to fully absorb.

In terms of absorption time, two extreme examples are pure glucose tabs and pizza. Pure glucose tabs are already glucose, so the body can absorb them with little digestive process. Pizza, on the other hand, is high in both carbs through crust and in fat and protein through cheese and toppings, resulting in total digestion time of upwards of five hours more.

When we talk about glucose for T1D, we are referring to glucose concentration, not raw amount of glucose. So 1g of carbs for a person who weighs 200 lbs will raise their glucose by 3 mg/dl, whereas the same amount of carbs for a person who weighs 100 lbs will result in a rise of 5 mg/dl given the lower blood volume.

5.2. Insulin semantics

Strictly speaking, insulin in the bloodstream lowers glucose levels by carrying glucose molecules from the blood to the liver, brain, muscles, or stored as fat cells for later use.

In people with a healthy pancreas, their pancreas detects the digestive process and secretes an appropriate amount of insulin directly into the blood stream.

In contrast, people living with T1D inject insulin into the tissue layer beneath the skin, so the insulin needs to travel from this sub dermal layer to the bloodstream where it can attach to glucose molecules, which takes longer than the pancreas.

Although the pancreas is good at matching insulin to glucose, it is not perfect. Healthy people still experience a rise in glucose when they eat high carb meals and can experience low glucose.

5.3. Synthetic insulin activation

The three main concepts for treating T1D using insulin are insulin on board, insulin sensitivity, and insulin activation curves. *Insulin on board* defines the amount of injected insulin that has *not* yet attached to glucose molecules. This insulin will activate over the next six hours and attach to a proportional amount of glucose. The net effect of insulin attaching to glucose molecules is lowering glucose levels.

Insulin sensitivity defines how much of a glucose drop one would expect if they took an international unit (or unit (U)) of insulin. For example, if one's insulin sensitivity is 42 mg/dl / U, then each unit of insulin injected in their body will reduce their glucose by 42 mg/dl over the next six hours.

The rate at which insulin drops glucose during the sixhour absorption period is defined by an exponential *insulin* activation curve. Typical insulin will take around 10 minutes to start acting, peak anywhere between 55 minutes to 75 minutes depending on the type of insulin and taper out over the final five or so hours of activation. Insulin makers publish insulin activation curves for the insulin they produce.

| Glucose level | Importance | | |
|---------------|--|--|--|
| 55 mg/dl | Below 55 mg/dl is considered severe low glucose | | |
| 70 mg/dl | Below 70 mg/dl is considered mild low glucose | | |
| 82 mg/dl | The average glucose for healthy people pre meal | | |
| 90 mg/dl | Our pre-meal glucose target for people living with T1D | | |
| 137 mg/dl | The average peak glucose for healthy people post meal | | |
| 140 mg/dl | Our goal for peak glucose for people living with T1D | | |
| 180 mg/dl | Above 180 mg/dl is considered high glucose | | |
| 250 mg/dl | Above 250 mg/dl is considered severely high glucose | | |

Figure 5. Important glucose levels.

5.4. Using insulin to manage T1D

When using insulin to manage T1D, people need to consider both the overall impact of the insulin as well as the dynamic response.

To cover a meal with insulin (bolus), a typical insulin treatment regime will require counting carbs for the meal, calculating the amount of insulin needed overall, and then timing the insulin dose to match carb absorption. For meals with fast acting carbs, people will dose before they eat by 15 minutes or more, sometimes call pre-bolusing. For slower absorbing carbs they dose when they eat. For even slower absorbing meals (e.g., pizza), they will commonly split their insulin dose into two or more bolus injections to match the timing of their meal.

Counting carbs is hard and sometimes people living with T1D get it wrong. If they dose too much insulin, it results in hypoglycemia (low glucose) and they need to eat more carbs to correct it. If they dose too little, they need to provide a *correction*, which is an additional insulin dose to bring their glucose back into range.

In addition to covering meals and correction doses, people living with T1D also need to supply a baseline of effectively constant insulin (*basal insulin* or basal) to account for the glucose that one's body produces naturally. Any insulin dosing to cover meals or provide corrections are in addition to this baseline basal rate.

To help manage their T1D, people's doctors typically provide therapeutic settings to help guide their calculations. These settings include their basal rate, carb-to-insulin ratio, and insulin sensitivity. With these settings, they use insulin to manage their T1D.

5.5. Important glucose levels

Figure 5 outlines meaningful glucose levels with a description of their importance. We show levels for healthy individual as well as the targets we set for MOS. We differentiate between glucose levels before someone eats (pre-meal) and for the 2-3 hours after they eat (post-meal).

6. T1D management strategy

This section outlines the fundamentals of our T1D management strategy. At its core our strategy is biohacking.

We combine, diet, physical activity, and automated insulin therapy to formulate our strategy for managing T1D.

6.1. Tight glucose management is key

Our core hypothesis is that the key to avoiding health complications due to T1D is tight glucose management. However, our core hypothesis is shaky. People living with T1D had their organs attacked by their own immune system and most or all of the beta cells in their pancreas are dead. These facts of T1D will almost certainly have a direct impact on long-term health. There is nothing that people living with T1D can do about these facts.

People living with T1D do have control over their glucose levels and there is evidence that elevated glucose levels are connected with both negative short-term and long-term health effects [13] [18]. Informally, once Bob started taking insulin when he was first diagnosed, he immediately felt better – he had more energy, was less cranky, he slept better – there is merit to maintaining tight glucose control. Our hypothesis is that people living with T1D can avoid negative long-term health outcomes, and reverse them if they have already started, with tight control over their glucose levels.

6.2. Glucose targets for tight control

Given that research has shown that elevated glucose levels increase risk of long-term complications, we first need to define normal glucose levels to set our targets. From a study done in 2007, researchers found that young, healthy, and lean people who wore CGMs had an average nighttime glucose level of 82 mg/dl with post-meal spikes peaking at 137 mg/dl on average after eating high glycemic-index foods [17].

Given that healthy, young, and lean people define the category of minimal risk for long-term health complications, we use their glucose levels as guidance for our target glucose range. However, at least 42 factors impact glucose levels [8], making management with CGMs and injected insulin challenging. Thus, we provide a bit of wiggle room for our pre-meal glucose range by setting our target at 90 mg/dl, while staying between 70 mg/dl and 120 mg/dl before meals. After eating, we try to keep our glucose levels between 70 mg/dl and 140 mg/dl.

6.3. Management examples and tradeoffs

To illustrate different management strategies and their tradeoffs, we provide three example strategies and cast them as a classic "pick two of three" problem.

The three goals that people living with T1D have are:

- Minimize long-term health complications due to T1D with tight glucose control.
- Minimize the cognitive load needed to manage their metabolic state.
- Minimize dietary restrictions.

| | Glucose | Cognitive | Dietary |
|---------------------------|--------------------------------------|-----------|--------------------------------------|
| | control | load | restrictions |
| Very low carb diet | $\stackrel{\wedge}{\Longrightarrow}$ | | |
| Sugar surfing adaptations | | 6 | $\stackrel{\wedge}{\Longrightarrow}$ |
| Set it and forget it | | * | |
| Our goal | $\stackrel{\wedge}{\Longrightarrow}$ | | |
| \$ | excellent, | e good | . 🙀 bad |

Figure 6. Three example T1D management strategies and the tradeoffs they make and our goal for our management strategy.

Our example strategies show how one can pick two of the three goals, but trade off the third. In practice there are a number of points in the overall management spectrum, but we do believe that making tradeoffs is fundamental.

Figure 6 shows three management strategies and their tradeoffs. The first strategy is to eat a very low carb diet [23]. The intuition behind this strategy is that eating fewer carbs requires less insulin. With fewer carbs and less insulin, individuals will experience smaller swings in glucose levels. With smaller swings in glucose levels, glycemic control is easier. Although this strategy provides the best glycemic control according to research, it brings with it substantial dietary restrictions, where effectively people using this strategy are on a Keto diet.

The second strategy is to constantly monitor CGM values and adapt to accommodate likely glycemic imbalance before it happens [33]. This basic strategy was introduced by Ponder and McMahon in their book titled "Sugar Surfing" [34]. With Sugar Surfing, people can eat whatever they want as long as they monitor their metabolic state and adapt by eating glucose, taking a brisk walk, or injecting more insulin, to account for how their body reacts. Although this strategy does away with dietary restrictions, it brings with it a substantial cognitive load from constantly monitoring glucose levels and reacting when needed.

The third strategy is to use an automated insulin delivery system and mostly ignore T1D. This basic strategy is epitomized by advances introduced by Beta Bionics [11], where their iLet automated insulin delivery system automatically learns one's insulin dynamics and injects insulin accordingly. In their clinical trial, the iLet system showed that it could make profound improvements to people with poor glycemic control. However, they were unable to improve individuals who had moderate control already. In the end, this management strategy does the most to reduce the cognitive load of managing T1D, but is unable to achieve the tight glucose control that we believe we need for minimizing long-term health complications.

6.4. Our approach

People will change their management strategies over time. For example, Bob used variants of all three of the example strategies we outline here and took with him the parts he liked while leaving behind the parts he disliked. And since people living with T1D are biohackers at their core, we expect their strategy to evolve with changes in their goals and as they learn more about their individual physiology.

Given our anticipation for change, rather than outlining a prescriptive management plan, we define the principles behind our basic strategy so that people can pick and choose which principles make the most sense for them.

Principle: Eat carbs with a low glycemic index

In our experience, eating foods with a low *glycemic index* is important for maintaining glycemic balance. Glycemic index measures how quickly carbs convert to glucose in the bloodstream, and eating foods with a low glycemic index are easier to manage, especially when using automated insulin delivery systems. For example, through experimentation Bob found that he can eat beans but not bread, farro but not rice, corn tortillas but not flour tortillas, and sweet potatoes but not russet potatoes. By eating low glycemic-index foods people can eat a medium carb diet while still maintaining tight control over their glucose.

Principle: Eat the same foods consistently and adapt insulin intake based on the past

One of our main management strategy goals is to minimize the cognitive load of managing T1D, and the time when the cognitive load is the highest is when eating. When eating, people living with T1D need to figure out what to eat, how much insulin to take, and when to take it. Eating a moderate amount of carbs and avoiding high glycemic-index foods helps with timing, so it really boils down to deciding what to eat and how much insulin to take. For both of these decisions we have found that consistency is key to reducing the cognitive load while maintaining tight glucose control.

We recommend eating the same 20 or so foods over and over again and using biohacking software to make it easier to calculate insulin dosing based on the past. At mealtime, review the past few times you ate the same meal and look at insulin dosing and the resulting glucose after the meal to figure out how much insulin to take and the timing. If your glucose stayed within your targets, take the same amount of insulin. If you had a glucose spike or hypoglycemia, adjust accordingly.

Principle: Exercise vigorously every day to reduce insulin needs

Exercise requires muscle contractions, which takes glucose, thus lowering your overall insulin needs. The effects of exercise are both immediate, as you are working out, and also carry over post exercise for as many as 48 hours as your body refills its glycogen stores. It adds some unpredictability while working out, so we wrote an app that tracks standard exercise stats *and* glucose in real time to help people adapt while working out.

The net effect of exercise is increasing insulin sensitivity. Increasing insulin sensitivity comes with lower insulin dosing needs, which helps make it easier to maintain glycemic balance, especially when using an automated insulin delivery system.

Principle: Technology amplifies the effectiveness of biohacking

The main overarching theme in all of our principles is using technology to amplify our efforts. Whether it is from an app for recording data after eating or an Apple Watch app for showing glucose while working out, technology and biohacking software help make it easier to manage T1D.

The most important technology is automated insulin delivery systems. These closed-loop systems help with adaptations. The human body is complex, and one's response to food can change from one day to the next in ways that are difficult to anticipate. Having an automated insulin delivery system adjust to these differences helps maintain tight control with a lower cognitive load.

6.5. Tying it together with an example

Figure 7 shows one example where Bob ate high glycemic-index foods and used our software to adapt. This figure shows two separate times that Bob ate a bagel sandwich from Noah's Bagels. The first time he ate this meal (screen shot on the left) he took a four-unit bolus ten minutes before he ate. When his glucose levels went above his postmeal target range, he took two 25-minute walks and still was unable to bring his glucose levels back down to his pre-meal upper bound of 120 mg/dl. The next time he ate this meal (screen shot on the right) he took a five-unit bolus and gave himself 40 minutes before eating. With this adjustment, he both avoided the post-meal spike and kept his glucose in range as his meal digested.

This example highlights the principles in our approach. First, it shows why we recommend avoiding high glycemic-index foods that are high in carbs. When you do, typical adjustments are less effective. Second, it shows that if you do want to eat high glycemic-index foods that are high in carbs, eating the same meals consistently and using past data helps to adjust dosing the next time around. Third, technology is at the center of this entire process.

7. Experiences

One of the biggest challenges in managing T1D is the variability in people's metabolic response to life. Differences

Figure 7. An example of applying our principles in practice.

in exercise, timing of insulin and eating, macro nutrient combinations, stress, caffeine, and so on all have an unpredictable impact on people's glucose levels.

To cope with these differences, closed-loop automated insulin delivery systems monitor glucose levels in real time and adjust insulin to compensate automatically. If an individual's glucose level is likely to go low, the system will shut off insulin to bring their glucose levels back up using their body's background glucose production. If their glucose levels are likely to go high, it will inject insulin. These automatic adjustments are what make closed-loop systems so effective at managing T1D.

In this section, we provide a qualitative description of our experiences designing, implementing, and running MOS. We cover our core algorithm development and iterations, and report on our experiences using iOS for a security-critical app. Section 8 describes our quantitative evaluation.

Our overarching principle is that we focus on usefulness to the human using MOS. At our core, the actions we take are specifically for the human who is living with T1D. We start from problems *they* have and design systems to solve these problems.

We have been working with one individual, who we will call Bob, for six months as we design and implement this system. Bob used the Metabolic Watchdog for the entire six months and used our closed-loop system for one week. Based on Bob's feedback and results, we iterate on our design.

Figure 8. Overview of the Metabolic Watchdog.

Without the metabolic watchdog

Watchdog predicts hypoglycemia in real time for proactive treatment

Figure 9. Preventing low glucose with the Metabolic Watchdog.

7.1. Metabolic Watchdog algorithms

Our high-level goal for our Metabolic Watchdog is to send a nudge to people before they experience glycemic imbalance automatically (Figure 8). Glycemic imbalance is when a person's glucose level drops below 70 mg/dl or rises above 180 mg/dl. When the algorithm detects likely glycemic imbalance, it sends a nudge using a push notification we send to the individual's Apple Watch and iPhone. Conceptually, these nudges play the same role that a closed-loop algorithm plays in an automated insulin delivery system, but for people running open-loop (e.g., manual injections using a syringe).

To maintain simplicity for the BioKernel, we run the Metabolic Watchdog as a separate app, outside of the core BioKernel.

The ideal nudge is both timely and actionable so they can correct the likely imbalance before it happens and only get alerts when there is an action they can take to correct it. Figure 9 shows the difference in glucose levels for an individual experiencing low glucose levels without the Metabolic Watchdog and using the Metabolic Watchdog. With traditional level-based alerting, the individual would be notified once they have already experienced low glucose levels, but with the Metabolic Watchdog they receive a notification on their Apple Watch indicating that they are likely to experience hypoglycemia without intervention, providing them with enough time to correct before their glucose level goes low.

Algorithmically, glucose prediction has been well studied in the literature [3]. Our contribution is showing how simple prediction models are effective in practice, obviating the need for more complex predictions, and how we need to consider insulin on board in our formulation.

To predict glycemic imbalance, we use a linear regression model that looks 15 minutes into the future. If we detect glycemic imbalance in the future, we nudge the individual.

This simple prediction for low glucose worked, but predictions for high glucose took a few iterations. We noticed that Bob would sometimes experience low glucose after treating for high glucose by taking a brisk walk. The root cause was that Bob had enough insulin on board to compensate for his elevated glucose levels. Updating our high prediction algorithm to account for insulin on board in addition to our glucose prediction eliminated these false positive alerts.

One surprise with the prediction for low glucose was that our simple model was effective. In practice, Bob effectively never faced a false negative (missing low glucose) when using our model. We had anticipated needing to use a more sophisticated model and using the simple model as a baseline. But, after getting real-world experience with the simple model, we found that it was good enough to solve Bob's problem of detecting low glucose before it happened.

The Metabolic Watchdog also helped improve Bob's overall glycemic control, which we detail in our evaluation (Section 8).

7.2. Closed-loop algorithm motivation

One recent trend that we observe is the advent of ultrafast acting insulin. Over the last few years Lyumjev insulin and Fiasp insulin both provide the ability for insulin to go from injection to the blood stream up to 30% faster than more traditional fast-acting insulin [24].

With ultra-fast insulin action, it reduces the need for our algorithms to predict the future since it can simply react rather than predict. One concrete impact of this difference is that the BioKernel does *not* have an abstraction for carbohydrates. When carbs digest, the body converts food into glucose in the blood stream, and most or all other automated insulin delivery systems predict carbohydrate absorption to compensate. But given that we start with ultra-fast insulin, we choose to react to rising glucose levels rather

than predict, which simplifies our system because we avoid introducing an additional abstraction and avoid designing prediction algorithms in the BioKernel.

7.3. Closed-loop algorithm

In general, closed-loop algorithms work by reading the latest glucose value from the CGM every five minutes, calculating the difference between current glucose and a target glucose level, and adjusting insulin to reach the target.

To calculate the amount of insulin needed, we use a combination of the amount of insulin on board with the insulin sensitivity to determine the amount of insulin needed or the insulin surplus. Based on this calculation, we adjust the basal rate to compensate.

From the user perspective, we only ask the user to set two therapeutic settings: their minimum basal rate and their insulin sensitivity. Using these two settings we design algorithms that can compensate for changes in practice with these settings.

From a theoretical perspective, our algorithm for this closed-loop problem is a proportional controller from control theory (the "P" in a PID controller). The advantage of using control theory is that we can use the principled tools available for feedback control to analyze our system and reason about algorithmic tradeoffs mathematically.

From a practical perspective, our real-world deployment has uncovered several challenges that we address. First, we include a safety threshold where anytime the individual's glucose drops below 80 mg/dl, we shut off insulin delivery. The transitions between the shut off state and closed loop control need to be handled carefully because the insulin on board values will continue to decrease while the system suspends insulin delivery, so when the closed loop algorithms turn back on the state of the system is different¹. Second, basal rates change throughout the day, and by using a proportional controller the system will reach a steady state equilibrium with a persistent error, which we observed with Bob. In other words, we can set our target glucose level for 90 mg/dl, but if the actual basal rate is lower than what we have configured, it will stabilize at a lower steady-state value.

We are in the process of adding an additional controller that accumulates values as persistent errors happen (i.e., the "I" of a PID controller) to compensate, but we are still in the design phase for this new controller.

Using feedback control for closed-loop automated insulin delivery has been well studied in the literature [40], mostly in simulation or mathematically. Our contribution is using a simple algorithm that has the properties we care about for building a real closed-loop system that facilitates tight control over glucose levels for people living with T1D.

^{1.} In control theory, there is a similar concept called *integrator windup*, which happens from non-linear behavior in the system.

7.4. Experience using iOS for MOS

Overall, we are happy with iOS as a platform for running MOS. The development tools are solid, the libraries are easy to use and provide clean abstractions, and the overall security model for iOS, with strong isolation between apps, is a match for our overall design.

There are three main areas, where based on our experiences, could be improved to support this type of system. First, we use Apple's Structured Concurrency abstractions for synchronization. Conceptually, using Structured Concurrency is similar to using a Mesa monitor with compiler support to eliminate data races. We generally liked using Structured Concurrency and feel that it helped us simplify our BioKernel implementation. However, the one aspect that we believe might be problematic is that, like monitors, when an actor object makes an async call, it gives up the lock and the internal state of the object can change before the caller reacquires the lock and continues running. These semantics mean that people need to ensure that their internal object state is consistent before calling an async routine and they need to recheck any assumptions when it returns because the object's state can change. For experts who are experienced using monitors this type of reasoning is appropriate, but it might be difficult for people who are less experienced using monitors.

Second, Apple's support for background execution doesn't support periodic tasks well. Our first version of the Metabolic Watchdog ran completely on device, using background execution to wake up every five minutes and run predictions. In practice, these periodic tasks can take an hour or more for the next invocation. For Bob, this meant that in our first implementation there were a few cases where alerts should have fired but did not due to the scheduling policy. These missing alerts caused Bob to lose trust in the system, so we moved to a cloud-based implementation. We believe that there are abstractions that iOS could support to facilitate this style of computation, but the current abstractions are not suitable. In contrast, the BioKernel does have reliable run time invocation because it uses the external Bluetooth devices to notify iOS to run tasks in the background for the BioKernel.

Third, Bluetooth access control is too broad, which has both advantages and disadvantages. In iOS, apps request broad Bluetooth permissions, which gives them access to all Bluetooth devices. This level of access is an advantage because we can access the CGM at the same time as the CGM manufacturer's app, which is a fundamental requirement for running an automated insulin delivery system. However, this also means that any apps with Bluetooth access can access the insulin pump, which is problematic. Ideally, we would like to have app-level permissions for certain classes of devices, like CGMs and insulin pumps.

8. Evaluation

In this section, we evaluate MOS. Our core hypothesis is that we can design a system for biohacking and managing

T1D using security first principles from the start, which has a simple implementation yet still supports tight control over T1D.

For our evaluation, we use data from one individual, who we will call Bob, who has been using MOS for the last six months to manage his T1D. We show results for Bob's average daily glucose, the primary measure of glycemic control for people living with T1D, for six months preceding his use of the Metabolic Watchdog and then for his first four months using it to compare. We also show results for one week's worth of data when Bob was running the BioKernel to manage his T1D using our closed-loop algorithms. We also compare the complexity of our BioKernel implementation against another open-source automated insulin delivery system, Loop.

From a therapeutic goals perspective, Bob is striving to achieve glycemic control that is in line with healthy individuals, which is more aggressive than what the American Diabetes Society outlines. The reason he wants to be aggressive is that when he was diagnosed in 2022, he had already incurred long-term damage from elevated glucose levels before diagnosis. Now that he has a T1D diagnosis, he tries to maintain glucose levels that are consistent with healthy people, while minimizing the cognitive load needed to do so.

Bob is a person living with T1D and must inject insulin every day, which is risky. He already takes on the inherent risk of putting his life in the hands of medical devices and injecting dangerous hormones. He is an enthusiastic biohacker and constantly running experiments on himself. All of this is just Tuesday for Bob.

Bob was unwilling to use Loop, another automated insulin delivery system. He felt that Loop was too complex and did not want to have that level of complexity controlling his insulin pump. When we introduced Bob to MOS, he enthusiastically volunteered to run the first version of our software ready for human use.

To run our experiments, we use MOS running on Bob's iPhone 14. Bob uses a Libre 3 CGM and a combination of manual insulin injections using a syringe and Humalog insulin in addition to insulin injections from a Omnipod Dash insulin pump with Lyumjev insulin. Bob also wears an Apple Watch, which we use to deliver notifications from the Metabolic Watchdog.

8.1. Ethical considerations

Since this study is an n=1 evaluation, and Bob is a willing and enthusiastic participant, we do not need to go through the IRB process. However, to ensure that we avoid putting Bob at risk, we went over our plan in detail with his endocrinologist, diabetes educator, and dietitian. Also, we got feedback from a sports medicine doctor and an emergency room doctor. Plus, we asked Bob to go over the plan with his therapist to ensure that these experiments avoid mental health issues.

All in all, we understand the gravity of having humans inject dangerous hormones using our software and have

Figure 10. Daily average glucose for Bob with annotations about life events and biohacking experiments. These results show tighter glycemic control once Bob started using the Metabolic Watchdog.

taken steps to consult outside experts to ensure that what we are doing makes sense from a medical perspective.

8.2. Glycemic control with the Metabolic Watchdog

Figure 10 shows Bob's daily average glucose level, the rolling 28-day average, and has annotations to highlight key events during this time. Bob's first attempt at controlling glucose levels closer to the non-diabetic range was when he tried eating a very low carb diet (60g or less of carbs per day) in early 2023. Although his glucose results were what he was looking for, he did not like restricting his diet so severely and anecdotally he felt tired while eating so few carbs (he exercises a lot). People have reported that the tired feeling goes away, but the dietary restrictions alone were enough for him to cut that experiment short.

In mid-March 2023, Bob's pancreas stopped producing insulin, forcing him to cover all meals and reduce his carb-to-insulin ratio drastically (previously he could eat 20g-30g of carbs without needing to bolus). When people are first diagnosed with T1D they often continue to produce a small amount of insulin, during what is referred to as the "honeymoon period," which ended for Bob in March 2023.

During late March and early April, Bob took a few weeks off work to spend some time learning about the fundamentals of diabetes management, and during this time he looked at his CGM data constantly. As a result, he was able to manage his glucose effectively.

In April, Bob went back to work, and his control suffered as he was unable to micromanage his glucose levels all day.

Figure 11. GMI for Bob compared to GMI levels for Prediabetes and Type 2 Diabetes. These results show that Bob has nearly the same average glucose level as a healthy individual, despite living with T1D.

In early May, Bob started using the Metabolic Watchdog to help improve his glycemic control.

Figure 11 shows Bob's GMI [7], which approximates A1C numbers based on CGM data. It shows Bob's GMI for a 28-day rolling average of his glucose levels. At its peak, his GMI was 6.8% and after using the Metabolic Watchdog in early May 2023 his GMI settled into the 5.7% - 5.9% range consistently. These average glucose levels are still in the low end of the "Prediabetes" range for people who have insulin resistance (i.e., Type 2 Diabetes), but at an acceptable level for Bob as someone living with T1D. These glucose levels are consistent with people who eat a very low carb

diet, which is the most effective management technique for T1D currently [23].

Since using the Metabolic Watchdog, Bob traveled to the American South (there was fried food everywhere), traveled internationally, worked in a high-stress job, worked out a ton, and got COVID. Despite these difficulties, Bob was able to maintain tight control for the entire period with decreasing cognitive load as we refined our software.

8.3. Maintaining glycemic control with the BioKernel closed-loop algorithm

During one week in late November 2023 - early December 2023, Bob ran the BioKernel closed-loop algorithm. His goal was to have the BioKernel automate some of the adaptations he made when using the Metabolic Watchdog alone. Thus, his goal for this experiment was to maintain the same level of control that we demonstrate in Section 8.2

Over this time, Bob had a GMI of 5.9%, which is consistent with the results obtained from our Metabolic Watchdog study. Anecdotally, Bob reported having to make fewer adaptations as the system adjusted insulin to accommodate his CGM readings. He continued to use the Metabolic Watchdog in concert with the closed-loop system.

8.4. BioKernel complexity

To evaluate the complexity of our BioKernel, we count the lines of code in our implementation and compare against Loop, another open-source automated insulin delivery system

Using the "cloc" utility the BioKernel app has 4.6k lines of code compared to 39.8k lines of code in the Loop app, an order of magnitude reduction. We omit the lines of code coming from LoopKit and other drivers because these are shared between both projects. However, LoopKit and the drivers have a substantial amount of code, weighing in at 70.1k lines of code and is likely the next big opportunity for simplification.

All those extra lines of code in Loop are useful, which is why we port Loop to run within MOS. Bob uses it for meal announcements and looking at their simulation and prediction results. However, for the core closed-loop algorithm we show how to keep it separated in an isolated protection domain while still providing the right interfaces to enable a fully featured automated insulin delivery system.

To explain why we have such a large reduction in source code, we outline the differences between the two systems. First, Loop has several features that we move outside of the BioKernel. These features include a remote interface for insulin dosing (which we think it a bad idea in general), a Watch app, Siri command interfaces, third party libraries, tutorials, meal announcements, physiological simulations, and predictions of future metabolic states. Second, we simplify our implementation of features that are shared between the BioKernel and Loop. These shared features include a

simplified local storage implementation, simplified concurrency support, minimal therapeutic settings, and a simplified closed loop algorithm. As our evaluation shows, we can still provide tight control over T1D with this simplified core system and still support most or all these additional features architecturally.

9. Related work

In addition to the research that we already mention in this paper, several other studies are also related to our work on MOS.

Several automated insulin delivery systems exist today. With companies such as Tandem, Insulet, Medtronic, and Beta Bionics all providing closed loop systems that connect CGMs to insulin pumps for automatic insulin delivery. From the open source world, OpenAPS [30] and Loop [26] also provide systems that people can use. Our study builds on top of these works, where we use many of the safety principles from OpenAPS, the software from Loop, and the push for user-facing simplicity from Beta Bionics. However, our focus is on how to decompose these monolithic systems into extensible and isolated components.

Previous research has looked at the security of implanted medical devices in general [21], [10], [37], in addition to looking at insulin pumps in particular [25], [32], with more recent work looking at providing improved security [28], [2]. Also, recent work has looked at applying formal methods to insulin pumps for high assurance [31]. These works focus on the device and their communication channel. In contrast, with MOS we assume that these devices are correct and secure and focus our efforts on the software we use to run the automated insulin delivery system while providing redundancy in case anything goes wrong.

In our BioKernel, we expose functionality through Universal Links where other apps can open UI views from the BioKernel to enable the individual to access the system. Work from Roesner et al [36] outlines how this can work securely on Android devices, and Flexdroid [39] shows how to provide more fine-grained isolation within an Android app.

10. Conclusion

Our audacious long-term goal is to turn a T1D diagnosis from a death sentence into an indicator of longevity, where people living with T1D will be expected to live longer then their healthy peers. This longevity will come by virtue of the tight control that they maintain over their metabolism through biohacking and advanced computer systems. Our first step towards this goal is to ensure that people can use trustworthy computer systems to manage their glucose levels.

In this paper, we showed how a clean slate approach to designing and implementing the new Metabolic Operating System led to a system built with security principles from the start, yet maintained the functionality needed to manage people's T1D. Our implementation was simple, keeping a spartan BioKernel app that managed the most critical parts of our overall system, while it provided event logs for other apps to consume so that they could contribute to the overall management problem safely.
